## $\mathsf{GARCH}\ \mathsf{Option}\ \mathsf{Pricing}^{\mathrm{a}}$

- Options can be priced when the underlying asset's return follows a GARCH process.
- Let  $S_t$  denote the asset price at date t.
- Let  $h_t^2$  be the conditional variance of the return over the period [t, t+1] given the information at date t.
  - "One day" is merely a convenient term for any elapsed time  $\Delta t$ .

<sup>a</sup>A Bloomberg quant said, on Feb 29, 2008, that GARCH option pricing is seldom used in trading.

## GARCH Option Pricing (continued)

• Adopt the following risk-neutral process for the price dynamics:<sup>a</sup>

$$\ln \frac{S_{t+1}}{S_t} = r - \frac{h_t^2}{2} + h_t \epsilon_{t+1}, \tag{66}$$

where

$$h_{t+1}^{2} = \beta_{0} + \beta_{1}h_{t}^{2} + \beta_{2}h_{t}^{2}(\epsilon_{t+1} - c)^{2}, \qquad (67)$$
  

$$\epsilon_{t+1} \sim N(0, 1) \text{ given information at date } t,$$
  

$$r = \text{ daily riskless return,}$$
  

$$c \geq 0.$$

<sup>a</sup>Duan (1995).

# GARCH Option Pricing (continued)

- The five unknown parameters of the model are  $c, h_0, \beta_0, \beta_1$ , and  $\beta_2$ .
- It is postulated that  $\beta_0, \beta_1, \beta_2 \ge 0$  to make the conditional variance positive.
- The above process, called the nonlinear asymmetric GARCH model, generalizes the GARCH(1,1) model (see text).

# GARCH Option Pricing (continued)

- It captures the volatility clustering in asset returns first noted by Mandelbrot (1963).<sup>a</sup>
  - When c = 0, a large  $\epsilon_{t+1}$  results in a large  $h_{t+1}$ , which in turns tends to yield a large  $h_{t+2}$ , and so on.
- It also captures the negative correlation between the asset return and changes in its (conditional) volatility.<sup>b</sup>
  - For c > 0, a positive  $\epsilon_{t+1}$  (good news) tends to decrease  $h_{t+1}$ , whereas a negative  $\epsilon_{t+1}$  (bad news) tends to do the opposite.

<sup>a</sup>"... large changes tend to be followed by large changes—of either sign—and small changes tend to be followed by small changes ..."

<sup>b</sup>Noted by Black (1976): Volatility tends to rise in response to "bad news" and fall in response to "good news."

### GARCH Option Pricing (concluded)

• With  $y_t \equiv \ln S_t$  denoting the logarithmic price, the model becomes

$$y_{t+1} = y_t + r - \frac{h_t^2}{2} + h_t \epsilon_{t+1}.$$
 (68)

- The pair  $(y_t, h_t^2)$  completely describes the current state.
- The conditional mean and variance of  $y_{t+1}$  are clearly

$$E[y_{t+1} | y_t, h_t^2] = y_t + r - \frac{h_t^2}{2}, \qquad (69)$$
  
Var $[y_{t+1} | y_t, h_t^2] = h_t^2. \qquad (70)$ 

# The Ritchken-Trevor (RT) Algorithm $^{\rm a}$

- The GARCH model is a continuous-state model.
- To approximate it, we turn to trees with *discrete* states.
- Path dependence in GARCH makes the tree for asset prices explode exponentially (why?).
- We need to mitigate this combinatorial explosion.

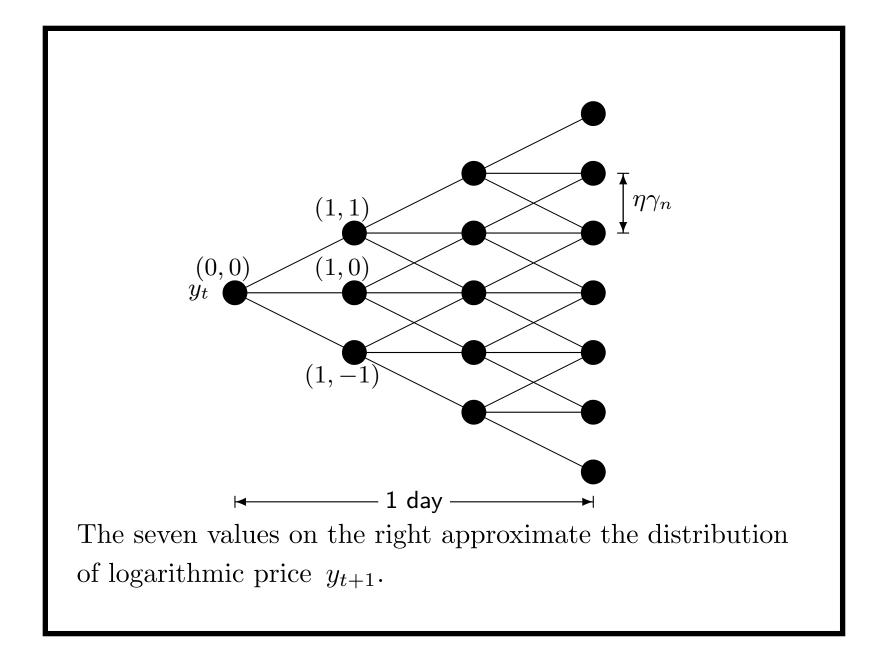

<sup>&</sup>lt;sup>a</sup>Ritchken and Trevor (1999).

- Partition a day into n periods.
- Three states follow each state  $(y_t, h_t^2)$  after a period.
- As the trinomial model combines, 2n + 1 states at date t + 1 follow each state at date t (recall p. 549).
- These 2n + 1 values must approximate the distribution of  $(y_{t+1}, h_{t+1}^2)$ .
- So the conditional moments (69)-(70) at date t+1 on p. 690 must be matched by the trinomial model to guarantee convergence to the continuous-state model.

- It remains to pick the jump size and the three branching probabilities.
- The role of  $\sigma$  in the Black-Scholes option pricing model is played by  $h_t$  in the GARCH model.
- As a jump size proportional to  $\sigma/\sqrt{n}$  is picked in the BOPM, a comparable magnitude will be chosen here.
- Define  $\gamma \equiv h_0$ , though other multiples of  $h_0$  are possible, and

$$\gamma_n \equiv \frac{\gamma}{\sqrt{n}}$$

- The jump size will be some integer multiple  $\eta$  of  $\gamma_n$ .
- We call  $\eta$  the jump parameter (p. 694).

- The middle branch does not change the underlying asset's price.
- The probabilities for the up, middle, and down branches are

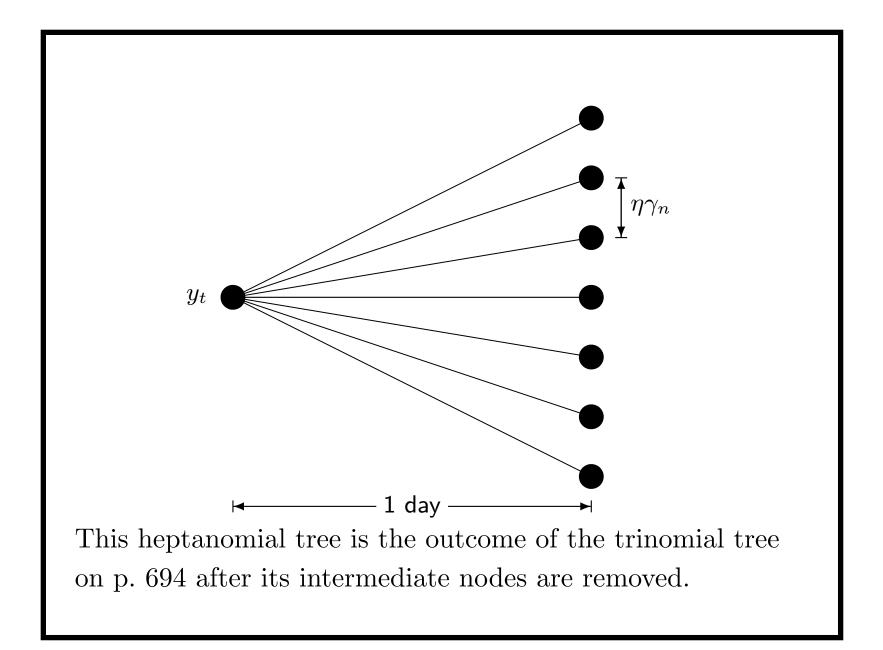

$$p_{u} = \frac{h_{t}^{2}}{2\eta^{2}\gamma^{2}} + \frac{r - (h_{t}^{2}/2)}{2\eta\gamma\sqrt{n}}, \qquad (71)$$

$$p_m = 1 - \frac{h_t^2}{\eta^2 \gamma^2}, \qquad (72)$$

$$p_d = \frac{h_t^2}{2\eta^2 \gamma^2} - \frac{r - (h_t^2/2)}{2\eta \gamma \sqrt{n}}.$$
 (73)

- It can be shown that:
  - The trinomial model takes on 2n + 1 values at date t + 1 for  $y_{t+1}$ .
  - These values have a matching mean for  $y_{t+1}$ .
  - These values have an asymptotically matching variance for  $y_{t+1}$ .
- The central limit theorem thus guarantees the desired convergence as *n* increases.

- We can dispense with the intermediate nodes *between* dates to create a (2n + 1)-nomial tree (p. 698).
- The resulting model is multinomial with 2n + 1branches from any state  $(y_t, h_t^2)$ .
- There are two reasons behind this manipulation.
  - Interdate nodes are created merely to approximate the continuous-state model after one day.
  - Keeping the interdate nodes results in a tree that can be as much as n times larger.

- A node with logarithmic price  $y_t + \ell \eta \gamma_n$  at date t + 1follows the current node at date t with price  $y_t$  for some  $-n \leq \ell \leq n$ .
- To reach that price in n periods, the number of up moves must exceed that of down moves by exactly  $\ell$ .
- The probability that this happens is

$$P(\ell) \equiv \sum_{j_u, j_m, j_d} \frac{n!}{j_u! j_m! j_d!} p_u^{j_u} p_m^{j_m} p_d^{j_d},$$

with 
$$j_u, j_m, j_d \ge 0, \ n = j_u + j_m + j_d$$
, and  $\ell = j_u - j_d$ .

• A particularly simple way to calculate the  $P(\ell)$ s starts by noting that

$$(p_u x + p_m + p_d x^{-1})^n = \sum_{\ell=-n}^n P(\ell) x^{\ell}.$$
 (74)

- So we expand  $(p_u x + p_m + p_d x^{-1})^n$  and retrieve the probabilities by reading off the coefficients.
- It can be computed in  $O(n^2)$  time.

- The updating rule (67) on p. 687 must be modified to account for the adoption of the discrete-state model.
- The logarithmic price  $y_t + \ell \eta \gamma_n$  at date t + 1 following state  $(y_t, h_t^2)$  at date t has a variance equal to

$$h_{t+1}^2 = \beta_0 + \beta_1 h_t^2 + \beta_2 h_t^2 (\epsilon_{t+1}' - c)^2, \qquad (75)$$

– Above,

$$\epsilon'_{t+1} = \frac{\ell \eta \gamma_n - (r - h_t^2/2)}{h_t}, \quad \ell = 0, \pm 1, \pm 2, \dots, \pm n,$$

is a discrete random variable with 2n + 1 values.

- Different conditional variances  $h_t^2$  may require different  $\eta$  so that the probabilities calculated by Eqs. (71)–(73) on p. 695 lie between 0 and 1.
- This implies varying jump sizes.
- The necessary requirement  $p_m \ge 0$  implies  $\eta \ge h_t/\gamma$ .
- Hence we try

$$\eta = \lceil h_t / \gamma \rceil, \lceil h_t / \gamma \rceil + 1, \lceil h_t / \gamma \rceil + 2, \dots$$

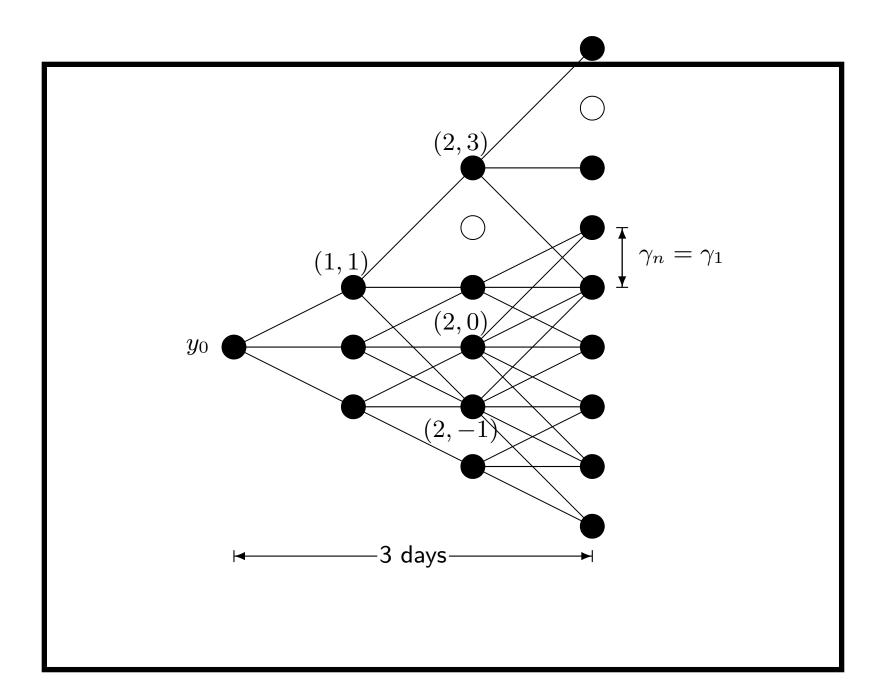

until valid probabilities are obtained or until their nonexistence is confirmed.

• The sufficient and necessary condition for valid probabilities to exist is<sup>a</sup>

$$\frac{|r - (h_t^2/2)|}{2\eta\gamma\sqrt{n}} \le \frac{h_t^2}{2\eta^2\gamma^2} \le \min\left(1 - \frac{|r - (h_t^2/2)|}{2\eta\gamma\sqrt{n}}, \frac{1}{2}\right)$$

- Obviously, the magnitude of  $\eta$  tends to grow with  $h_t$ .
- The plot on p. 704 uses n = 1 to illustrate our points for a 3-day model.
- For example, node (1,1) of date 1 and node (2,3) of date 2 pick  $\eta = 2$ .

<sup>a</sup>Lyuu and Wu (2003).

- The topology of the tree is not a standard combining multinomial tree.
- For example, a few nodes on p. 704 such as nodes (2,0) and (2,-1) have multiple jump sizes.
- The reason is the path dependence of the model.
  - Two paths can reach node (2,0) from the root node, each with a different variance for the node.
  - One of the variances results in  $\eta = 1$ , whereas the other results in  $\eta = 2$ .

- The number of possible values of  $h_t^2$  at a node can be exponential.
  - Each path brings with it a different variance  $h_t^2$ .
- To address this problem, we record only the maximum and minimum  $h_t^2$  at each node.<sup>a</sup>
- Therefore, each node on the tree contains only two states  $(y_t, h_{\text{max}}^2)$  and  $(y_t, h_{\text{min}}^2)$ .
- Each of  $(y_t, h_{\max}^2)$  and  $(y_t, h_{\min}^2)$  carries its own  $\eta$  and set of 2n + 1 branching probabilities.

<sup>a</sup>Cakici and Topyan (2000). But see p. 738 for a potential problem.

### Negative Aspects of the Ritchken-Trevor Algorithm<sup>a</sup>

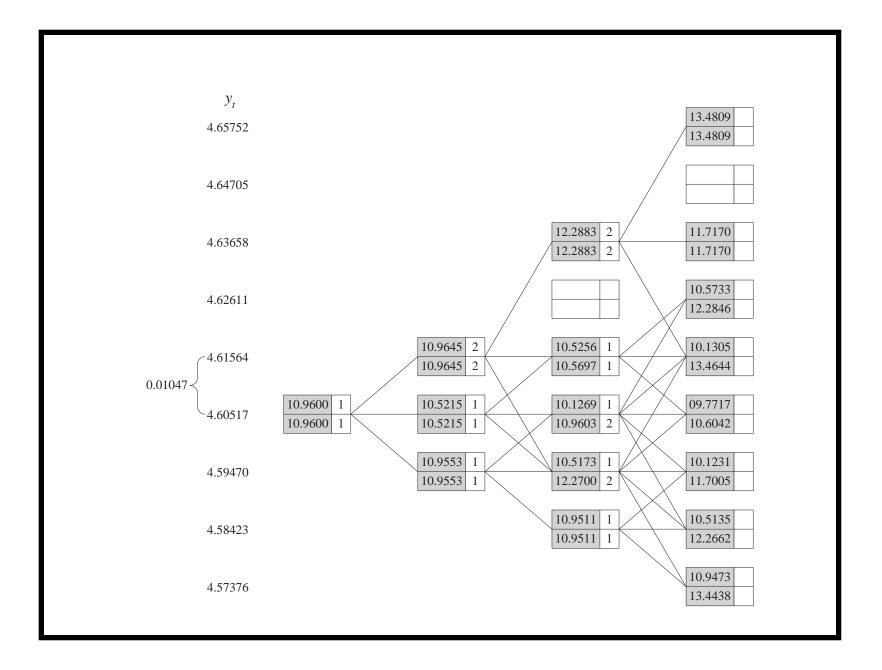

- A small n may yield inaccurate option prices.
- But the tree will grow exponentially if n is large enough. - Specifically,  $n > (1 - \beta_1)/\beta_2$  when r = c = 0.
- A large *n* has another serious problem: The tree cannot grow beyond a certain date.
- Thus the choice of n may be limited in practice.
- The RT algorithm can be modified to be free of shortened maturity and exponential complexity.<sup>b</sup>

<sup>a</sup>Lyuu and Wu (2003, 2005). <sup>b</sup>It is only  $O(n^2)$  if  $n \le (\sqrt{(1-\beta_1)/\beta_2} - c)^2!$ 

#### Numerical Examples

- Assume  $S_0 = 100, y_0 = \ln S_0 = 4.60517, r = 0,$   $h_0^2 = 0.0001096, \gamma = h_0 = 0.010469, n = 1,$   $\gamma_n = \gamma/\sqrt{n} = 0.010469, \beta_0 = 0.000006575, \beta_1 = 0.9,$  $\beta_2 = 0.04, \text{ and } c = 0.$
- A daily variance of 0.0001096 corresponds to an annual volatility of  $\sqrt{365 \times 0.0001096} \approx 20\%$ .
- Let  $h^2(i,j)$  denote the variance at node (i,j).
- Initially,  $h^2(0,0) = h_0^2 = 0.0001096$ .

- Let  $h_{\max}^2(i,j)$  denote the maximum variance at node (i,j).
- Let  $h_{\min}^2(i, j)$  denote the minimum variance at node (i, j).
- Initially,  $h_{\max}^2(0,0) = h_{\min}^2(0,0) = h_0^2$ .
- The resulting three-day tree is depicted on p. 710.

A top (bottom) number inside a gray box refers to the minimum (maximum, respectively) variance  $h_{\min}^2$  ( $h_{\max}^2$ , respectively) for the node. Variances are multiplied by 100,000 for readability. A top (bottom) number inside a white box refers to  $\eta$  corresponding to  $h_{\min}^2$  ( $h_{\max}^2$ , respectively).

- Let us see how the numbers are calculated.
- Start with the root node, node (0,0).
- Try  $\eta = 1$  in Eqs. (71)–(73) on p. 695 first to obtain

 $p_u = 0.4974,$   $p_m = 0,$  $p_d = 0.5026.$ 

• As they are valid probabilities, the three branches from the root node use single jumps.

- Move on to node (1,1).
- It has one predecessor node—node (0,0)—and it takes an up move to reach the current node.
- So apply updating rule (75) on p. 701 with  $\ell = 1$  and  $h_t^2 = h^2(0,0)$ .
- The result is  $h^2(1,1) = 0.000109645$ .

• Because  $\lceil h(1,1)/\gamma \rceil = 2$ , we try  $\eta = 2$  in Eqs. (71)–(73) on p. 695 first to obtain

$$p_u = 0.1237,$$
  
 $p_m = 0.7499,$   
 $p_d = 0.1264.$ 

• As they are valid probabilities, the three branches from node (1,1) use double jumps.

- Carry out similar calculations for node (1,0) with  $\ell = 0$  in updating rule (75) on p. 701.
- Carry out similar calculations for node (1, -1) with  $\ell = -1$  in updating rule (75).
- Single jump  $\eta = 1$  works in both nodes.
- The resulting variances are

 $h^2(1,0) = 0.000105215,$  $h^2(1,-1) = 0.000109553.$ 

- Node (2,0) has 2 predecessor nodes, (1,0) and (1,-1).
- Both have to be considered in deriving the variances.
- Let us start with node (1,0).
- Because it takes a middle move to reach the current node, we apply updating rule (75) on p. 701 with  $\ell = 0$ and  $h_t^2 = h^2(1,0)$ .
- The result is  $h_{t+1}^2 = 0.000101269$ .

- Now move on to the other predecessor node (1, -1).
- Because it takes an up move to reach the current node, apply updating rule (75) on p. 701 with  $\ell = 1$  and  $h_t^2 = h^2(1, -1)$ .
- The result is  $h_{t+1}^2 = 0.000109603$ .
- We hence record

$$h_{\min}^2(2,0) = 0.000101269,$$
  
 $h_{\max}^2(2,0) = 0.000109603.$ 

- Consider state  $h_{\max}^2(2,0)$  first.
- Because  $\lceil h_{\max}(2,0)/\gamma \rceil = 2$ , we first try  $\eta = 2$  in Eqs. (71)–(73) on p. 695 to obtain

 $p_u = 0.1237,$  $p_m = 0.7500,$  $p_d = 0.1263.$ 

• As they are valid probabilities, the three branches from node (2,0) with the maximum variance use double jumps.

- Now consider state  $h_{\min}^2(2,0)$ .
- Because  $\lceil h_{\min}(2,0)/\gamma \rceil = 1$ , we first try  $\eta = 1$  in Eqs. (71)–(73) on p. 695 to obtain

 $p_u = 0.4596,$  $p_m = 0.0760,$  $p_d = 0.4644.$ 

• As they are valid probabilities, the three branches from node (2,0) with the minimum variance use single jumps.

- Node (2, -1) has 3 predecessor nodes.
- Start with node (1,1).
- Because it takes a down move to reach the current node, we apply updating rule (75) on p. 701 with  $\ell = -1$  and  $h_t^2 = h^2(1, 1)$ .
- The result is  $h_{t+1}^2 = 0.0001227$ .

- Now move on to predecessor node (1,0).
- Because it also takes a down move to reach the current node, we apply updating rule (75) on p. 701 with  $\ell = -1$  and  $h_t^2 = h^2(1, 0)$ .
- The result is  $h_{t+1}^2 = 0.000105609$ .

- Finally, consider predecessor node (1, -1).
- Because it takes a middle move to reach the current node, we apply updating rule (75) on p. 701 with  $\ell = 0$ and  $h_t^2 = h^2(1, -1)$ .
- The result is  $h_{t+1}^2 = 0.000105173$ .
- We hence record

$$h_{\min}^2(2,-1) = 0.000105173,$$
  
 $h_{\max}^2(2,-1) = 0.0001227.$ 

- Consider state  $h_{\max}^2(2,-1)$ .
- Because  $\lceil h_{\max}(2,-1)/\gamma \rceil = 2$ , we first try  $\eta = 2$  in Eqs. (71)–(73) on p. 695 to obtain

 $p_u = 0.1385,$  $p_m = 0.7201,$  $p_d = 0.1414.$ 

 As they are valid probabilities, the three branches from node (2,-1) with the maximum variance use double jumps.

- Next, consider state  $h_{\min}^2(2,-1)$ .
- Because  $\lceil h_{\min}(2,-1)/\gamma \rceil = 1$ , we first try  $\eta = 1$  in Eqs. (71)–(73) on p. 695 to obtain

 $p_u = 0.4773,$  $p_m = 0.0404,$  $p_d = 0.4823.$ 

 As they are valid probabilities, the three branches from node (2,-1) with the minimum variance use single jumps.

## Numerical Examples (concluded)

- Other nodes at dates 2 and 3 can be handled similarly.
- In general, if a node has k predecessor nodes, then 2k variances will be calculated using the updating rule.
  - This is because each predecessor node keeps two variance numbers.
- But only the maximum and minimum variances will be kept.

### Negative Aspects of the RT Algorithm Revisited $^{\rm a}$

- Recall the problems mentioned on p. 707.
- In our case, combinatorial explosion occurs when

$$n > \frac{1 - \beta_1}{\beta_2} = \frac{1 - 0.9}{0.04} = 2.5.$$

- Suppose we are willing to accept the exponential running time and pick n = 100 to seek accuracy.
- But the problem of shortened maturity forces the tree to stop at date 9!

<sup>a</sup>Lyuu and Wu (2003).
