

Jointly Modeling Inter-Slot Relations by Random Walk on Knowledge Graphs for Unsupervised Spoken Language Understanding

Yun-Nung (Vivian) Chen, William Yang Wang, and Alexander I. Rudnicky

Summary

Experimental Results

Motivation

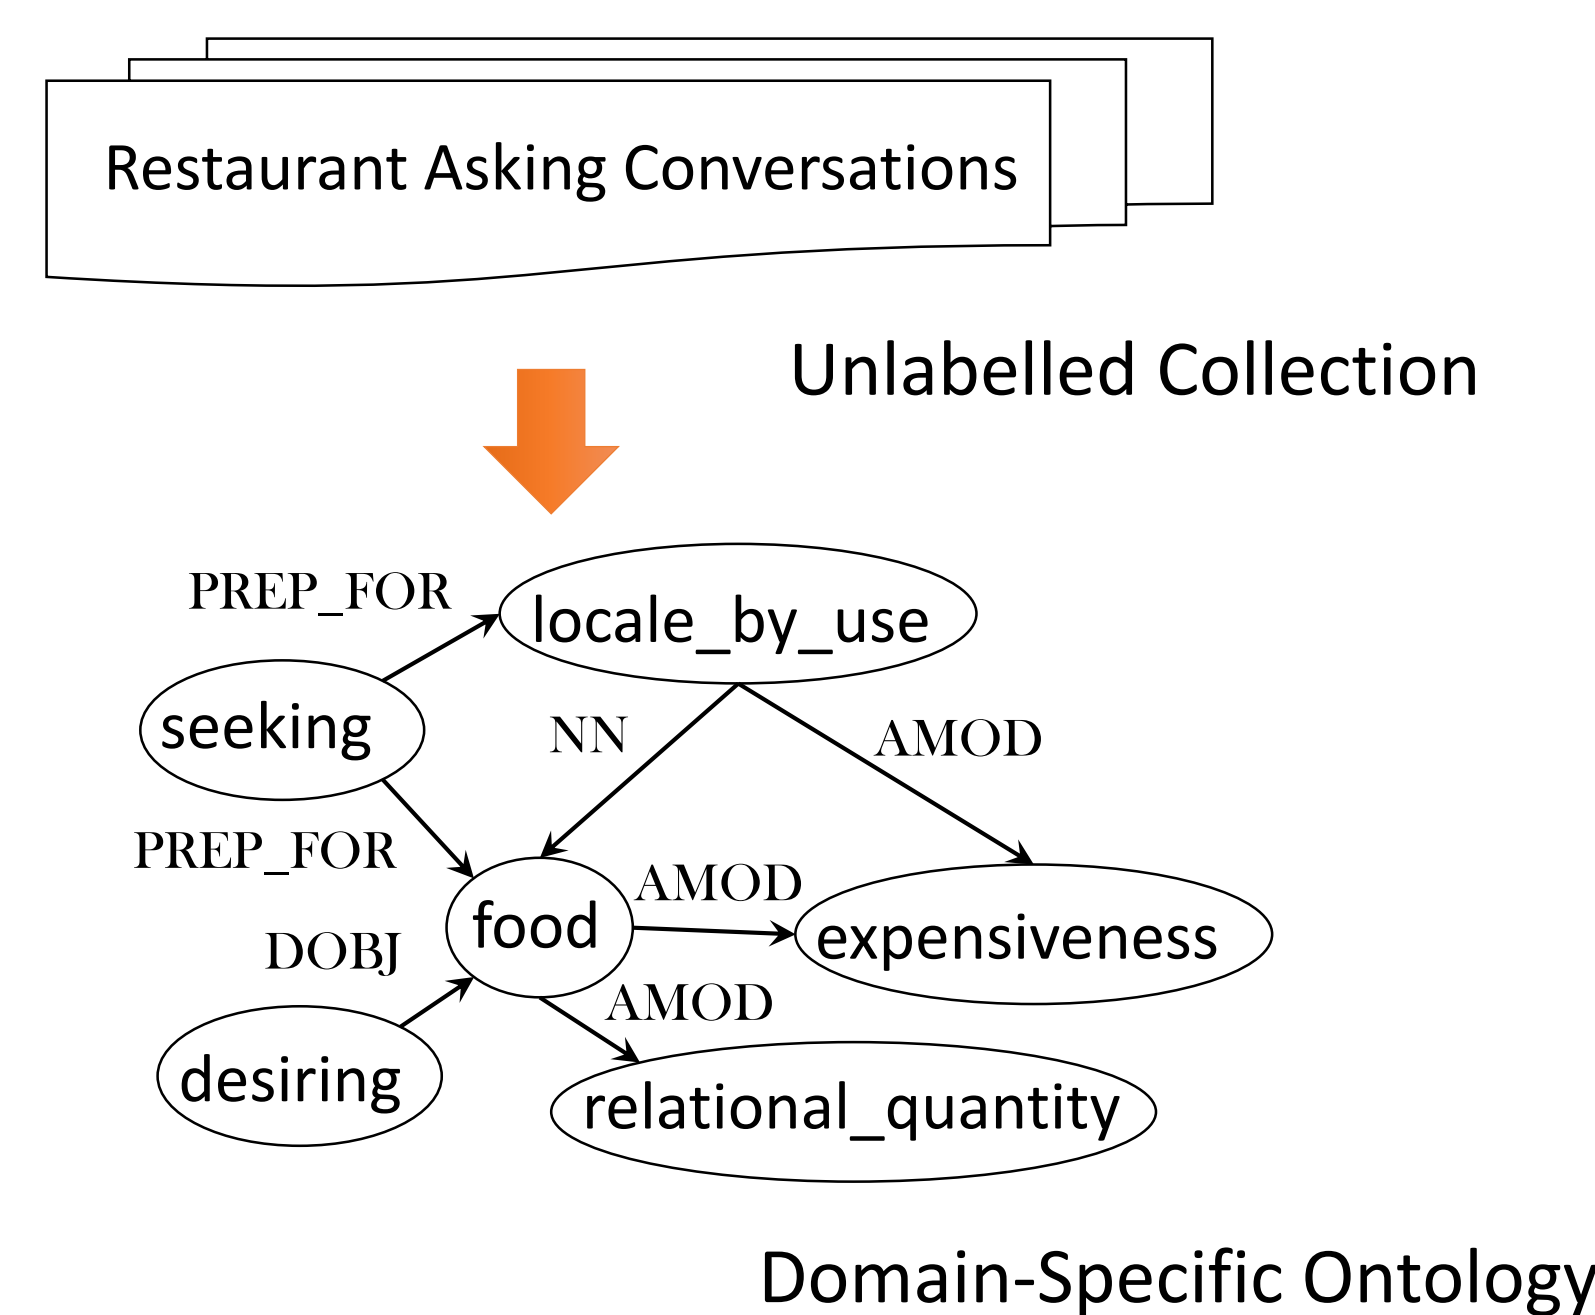

- SDSs require a predefined semantic ontology; can it be learned from data?
- Inter-slot relations can provide a coherent ontology
- Typed dependencies enable learning of ontology structure

Approach

- Construct two-layer knowledge graph represent slots, words, and relations
- Compute scores for edges (relations) and nodes (slots) by random walk
- Identify important slots associated with relations

Result

- Using embedding similarity, we achieve 70% AP for slot induction and 48% AF for SLU
- The automatically acquired slot set enhances the interpretability of semantic slots

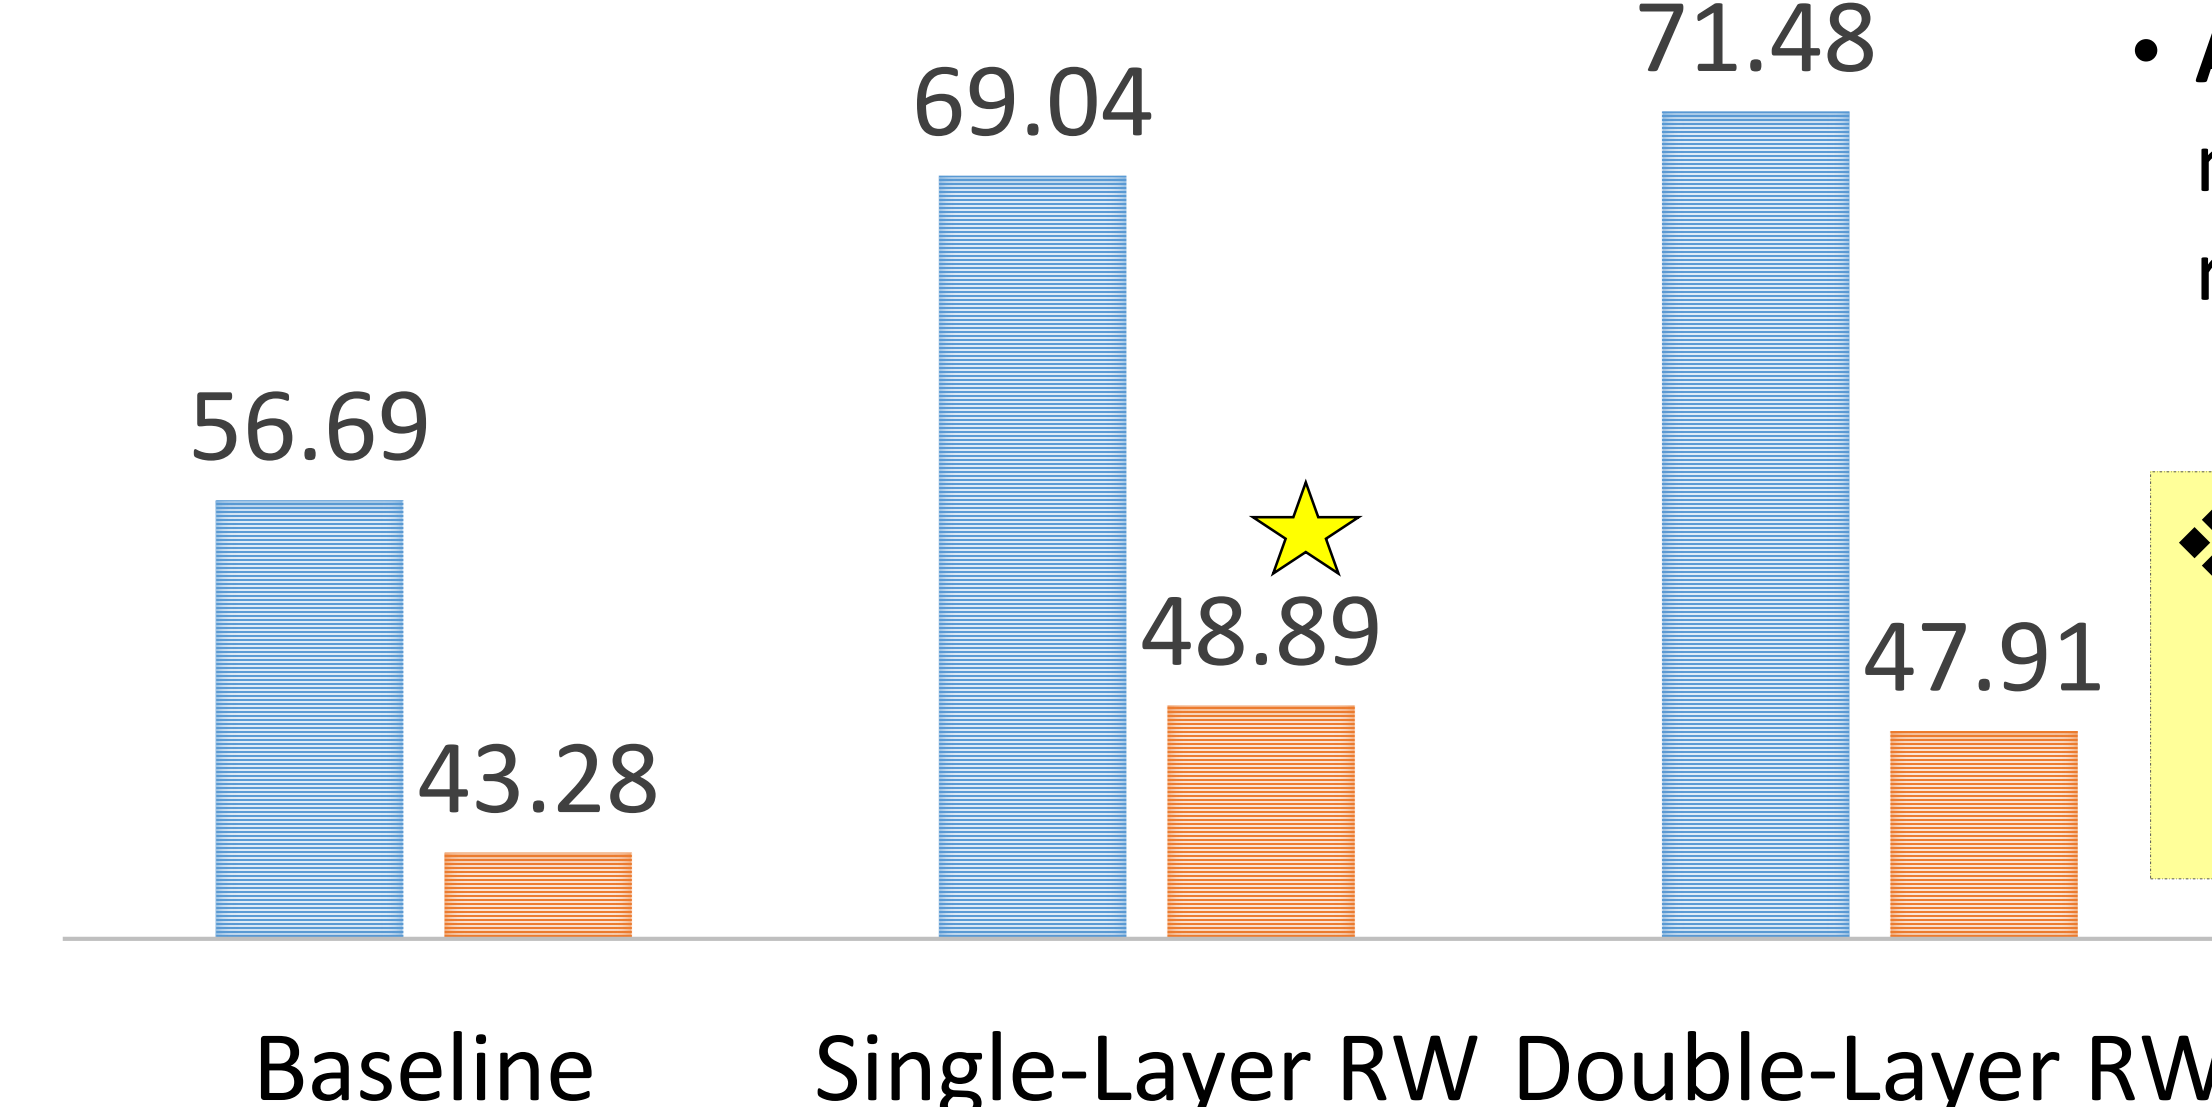

- Domain: restaurant recommendation in an in-car setting (WER = 37%)

- Dialogue slots: **addr**, **area**, **food**, **phone**, **postcode**, **pricerange**, **task**, **type**

Slot Induction (AP)

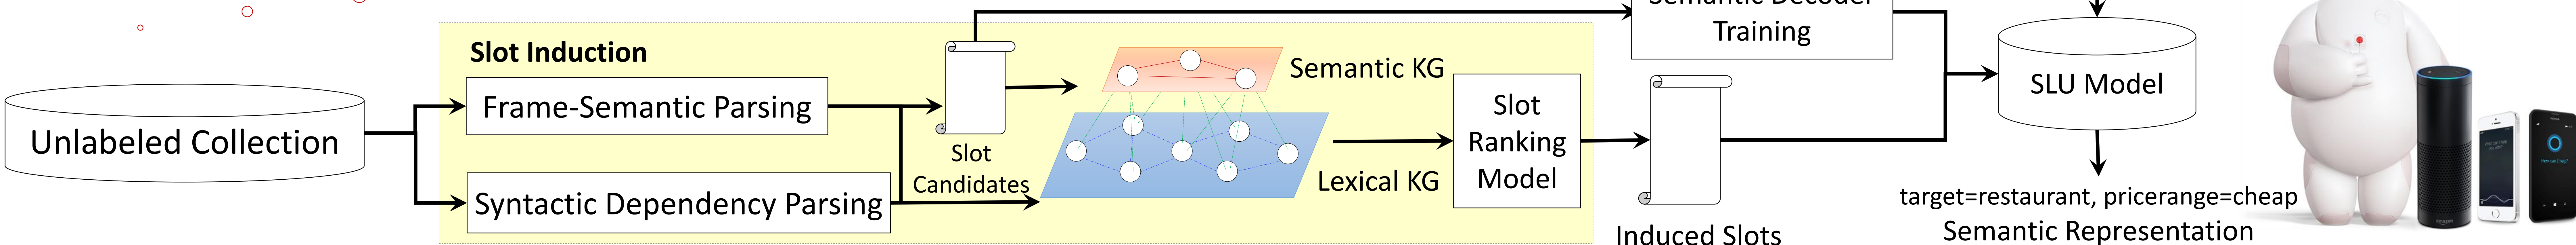

SLU (AF)

- AP**: Average Precision given a ranked list of induced slots and associated scores
- AF**: Average micro F-measure of SLU models at all cut-off positions in the ranked list

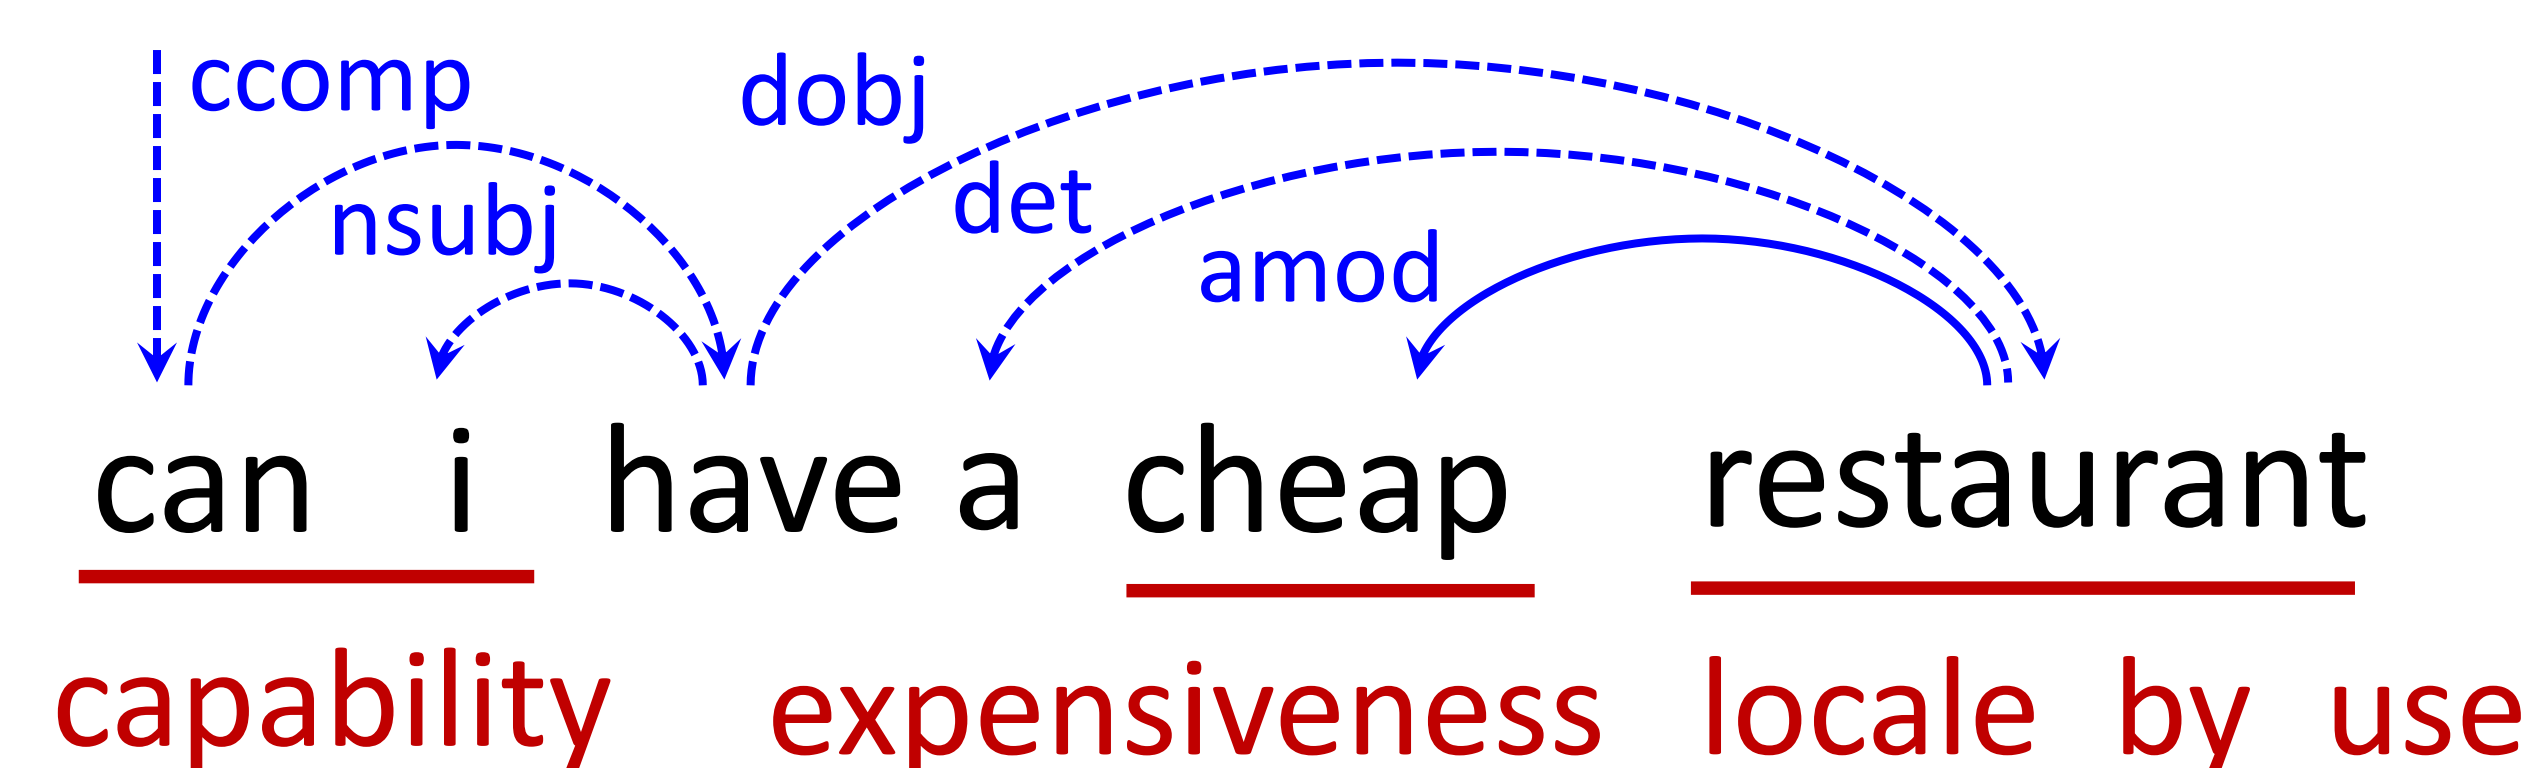

❖ The double-layer random walk performs best for slot induction and almost best for SLU.

Can a dialogue system automatically learn open domain knowledge?

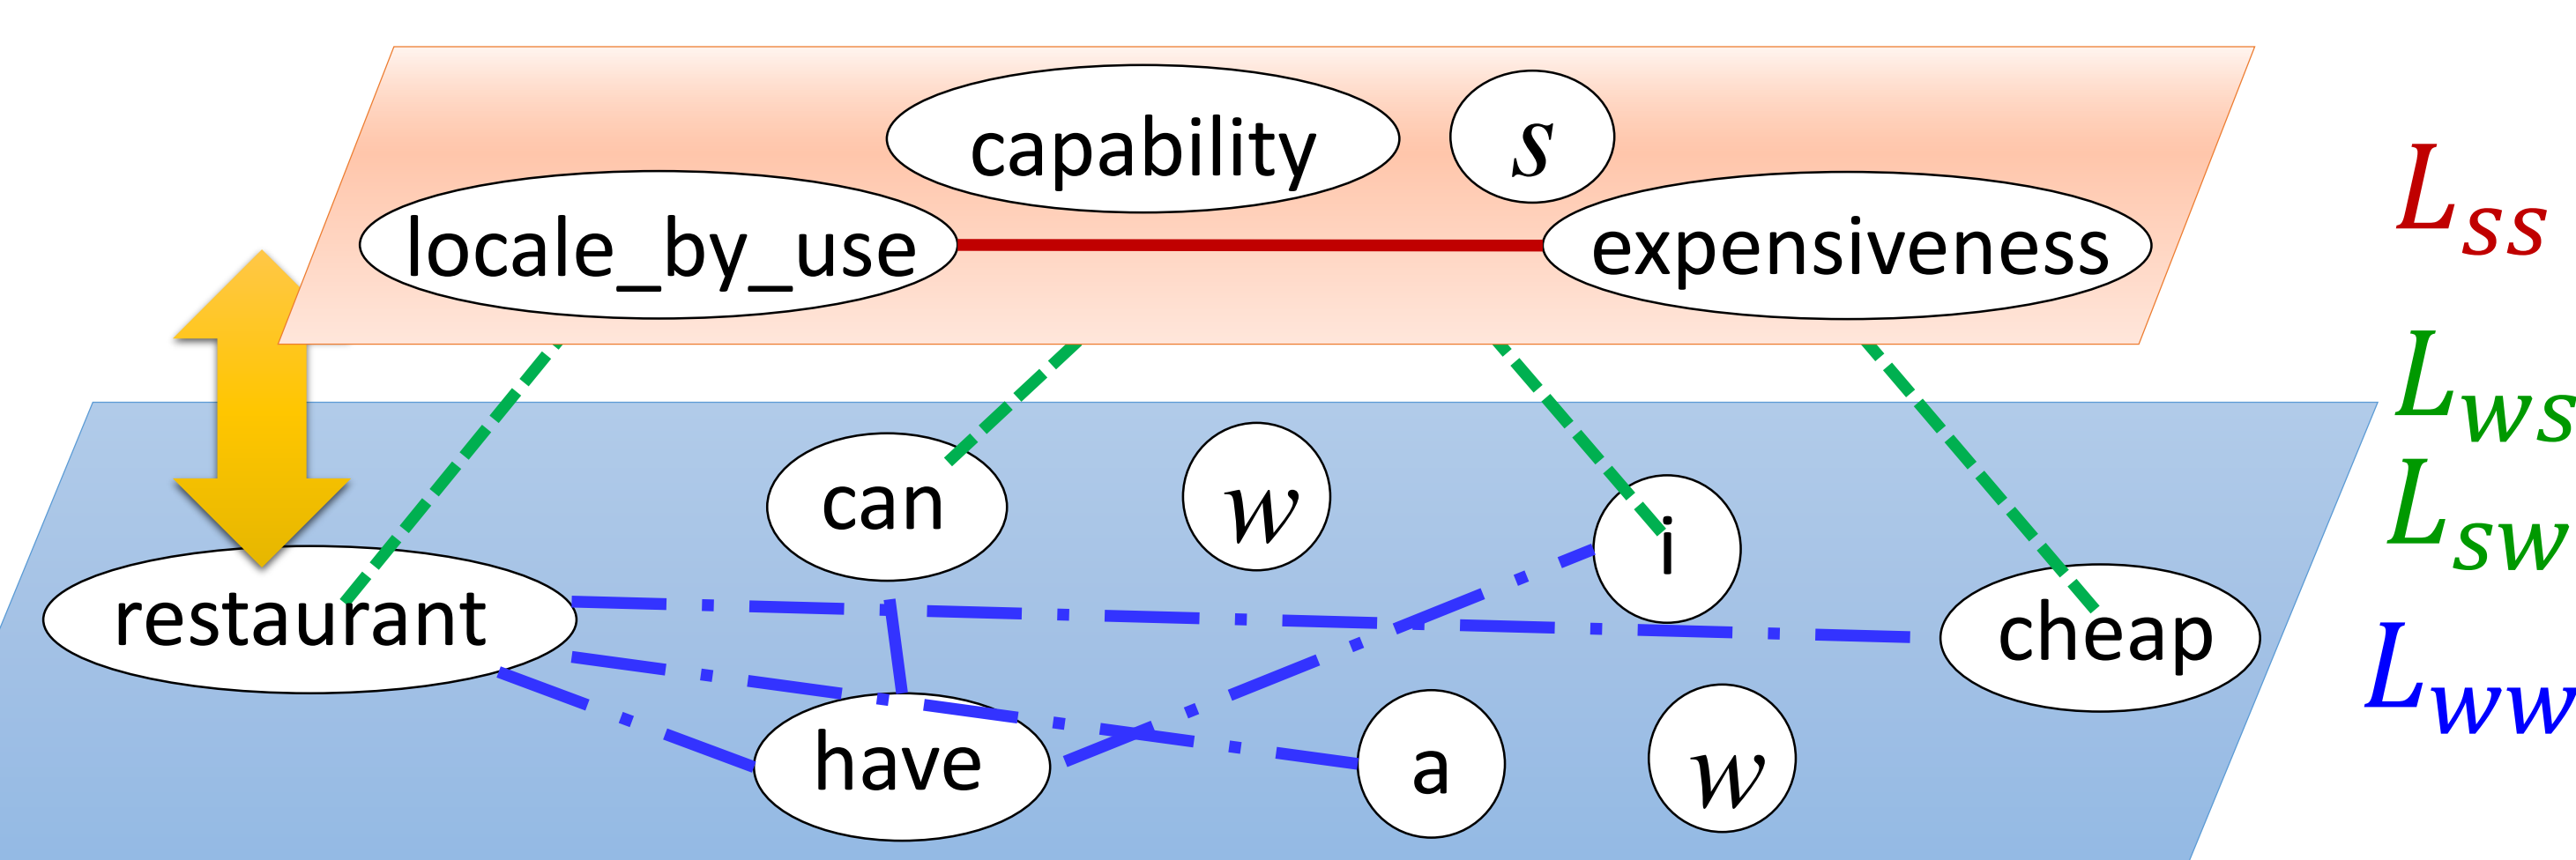

Step 1: Knowledge Graph Construction

Structure can be constructed via the unlabeled collection with **frame-semantic parsing** and **syntactic dependency parsing**.

Slot-Based Semantic KG

Word-Based Lexical KG

Step 2: Weight Measurement

Idea: the edge weights can represent the relation importance

- We train dependency-based word/slot embeddings [1].

Then the relation matrices can be built

- Slot-to-slot relation** L_{ss} : similarity between slot embeddings
- Word-to-slot relation** L_{ws} or L_{sw} : frequency of the slot-word pair
- Word-to-word relation** L_{ww} : similarity between word embeddings

Assumption: the slots with more dependencies to more important slots should be more important

The random walk algorithm computes the importance for each slot

$$\begin{cases} r_s^{(t+1)} = (1 - \alpha)r_s^{(0)} + \alpha L_{ss} L_{sw} r_w^{(t)} \\ r_w^{(t+1)} = (1 - \alpha)r_w^{(0)} + \alpha L_{ww} L_{ws} r_s^{(t)} \end{cases}$$

❖ The converged scores suggest whether the slots are important for this domain based on the automatically built structure [2].

Step 3: Domain Slot/Relation Identification

Converged slot importance helps us identify domain ontology:

- Rank slot pairs by summing up their converged scores
- Select slot pairs with higher scores according to a threshold

the reference ontology with the most frequent dependencies

locale by use	type	commerce scenario	price range
building		expensiveness	
food	food	range	
origin			
contacting	phone	part orientational	area
		direction	
seeking	task	locale	
desiring		part inner outer	
locating			
sending	postcode	speak on topic	addr
